## INTRODUCTION

### 1. DISTRIBUTIONS

**1.1. Distributions and Horizontal Curves.** A manifold without boundary  $M$  of dimension  $m$  is said to be of class  $C^\infty$  if the differentiability class of the transition maps is  $C^\infty$ . In this case, for every  $p \in M$  one can define the tangent space to  $p$ ,  $T_p M$ , as the set of all derivations of the algebra of germs of smooth functions from  $M$  to  $\mathbb{R}$ , based on  $p$ . This definition of tangent space is equivalent (when the differentiability class of  $M$  is  $\infty$ ) to the equivalence class of germs of curves that passes through  $p$ . If a manifold  $M$  is  $C^r$ , with  $r < \infty$ , the definition for tangent space is the latter, so we use that definition for the tangent space throughout this text, independently of the differentiability class.

Joining the tangent spaces of every point of the manifold induces the tangent bundle,

$$TM = \bigsqcup_{p \in M} T_p M,$$

equipped with manifold structure given by the one of  $M$ . It is called a bundle because the triple  $(TM, M, \pi : TM \rightarrow M)$  is in fact a bundle, where  $\pi : TM \rightarrow M$  is the projection function, that assigns each tangent vector to the point where it is based. Each fiber of this bundle is a tangent space based on a point, and the tangent bundle is in particular a vector bundle because each fiber has structure of finite dimensional real vector space. Moreover, the tangent bundle belongs to the class of smooth vector bundles, objects of particular interest in differential geometry.

**Definition 1** (Smooth Vector Bundle). The triple  $(E, M, \pi : E \rightarrow M)$  is a smooth vector bundle if  $E, M$  are smooth manifolds,  $\pi$  is a smooth surjection; the fibers  $\pi^{-1}(p)$  for  $p \in M$  have the structure of finite dimensional vector spaces; and for every point  $p \in M$ , there is an open neighborhood  $U$  of  $p$ , a natural number  $k$  and a diffeomorphism  $\phi : U \times \mathbb{R}^k \rightarrow \pi^{-1}(U)$ , such that for all  $q \in U$  the following propositions hold:

- $(\pi \circ \phi)(q, v) = q$  for all  $v \in \mathbb{R}^k$ , and
- the map  $v \mapsto \phi(p, v)$  is a linear isomorphism between the vector spaces  $\pi^{-1}(p)$  and  $\mathbb{R}^k$ .

For an arbitrary bundle  $(E, B, \pi : E \rightarrow B)$ , a subbundle of this bundle  $(E', B', \pi' : E' \rightarrow B')$  is just a bundle that satisfies  $E' \subset E$ ,  $B' \subset B$  and  $\pi|_{E'} = \pi'$ . In particular, a smooth vector subbundle is a vector subbundle that is also smooth.

**Definition 2** (Distribution). A distribution  $\mathcal{H}$  over a manifold  $M$  is a vector subbundle of the tangent bundle  $TM$ . If this vector subbundle is in addition smooth, the distribution is said to be smooth, and the rank  $k$  of this distribution is defined as the dimension of its fibers.

The fiber of  $\mathcal{H}$  at a point  $p \in M$  is denoted as  $H_p$ .

The concept of (smooth) distribution can be defined in an alternative but equivalent (see [1], Ch. 19) fashion using 1-forms, with the help of the following proposition.

**Proposition 1** (Smooth Distribution (using 1-forms)). *Suppose that  $M$  is a smooth  $m$ -dimensional manifold, and  $\mathcal{H} \subset TM$  is a distribution of rank  $k$ . Then  $\mathcal{H}$  is smooth if and only if for every point  $p \in M$  there is a neighborhood  $U$  of that point where exist  $n - k$  smooth 1-forms  $\omega^1, \dots, \omega^{n-k}$ , such that for all  $q \in U$ ,*

$$\mathcal{H}_q = \text{Ker } \omega^1|_q \cap \dots \cap \text{Ker } \omega^{n-k}|_q.$$

Some examples of distributions over manifolds are given below.

*Example 1* (Tangent Bundle). For any manifold  $M$ , the tangent bundle  $TM$  is by definition a distribution over it.

*Example 2* (Heisenberg Group). Take  $\mathbb{R}^3$  as the manifold, and define over it the distribution  $\mathcal{H} \subset T\mathbb{R}^3$ , whose fiber at an arbitrary  $(x, y, z) \in \mathbb{R}^3$  is

$$\mathcal{H}_{(x,y,z)} = \text{Ker } \omega|_{(x,y,z)},$$

where  $\omega = dz - (xdy - ydx)/2 \in \Omega^1(\mathbb{R}^3)$ .

*Remark 1.* The last example is of particular interest because of its connection with the isoperimetrical problem. For more information see [2], Ch. 1.

*Example 3* (Vector Field over a Manifold). Any smooth vector field  $X : M \rightarrow TM$  (which does not cancel out at any point) on a manifold determines a distribution  $\mathcal{H}$  over the manifold  $M$  whose fiber at an arbitrary  $p \in M$  is the span of  $X_p$ .

As a particular case of this example, one can consider a system of  $n$  linear differential equations on  $\mathbb{R}^n$  without equilibrium points, that determines a vector field over  $\mathbb{R}^n$ , and this in turn generates a distribution via the span of the vectors at each point.

Given a distribution  $\mathcal{H}$  over a manifold  $M$ , a curve or vector field is said to be **horizontal** if it is tangent to  $\mathcal{H}$ . This means that, in the case of a curve, its tangent vector at every point is contained in the fibers of  $\mathcal{H}$ ; and in the case of a vector field, its image at every point where it is defined is contained in the fibers of  $\mathcal{H}$ .

For example, every curve over a riemannian structure is horizontal. In the example 2, the liftings of the solutions of the isoperimetrical problem are horizontal. In example 3, and in particular in the case of systems of linear differential equations, the solution curves of the system of differential equations are examples of horizontal curves for that distribution.

**1.2. Frobenius' Theorem.** Now the natural question that arises is if, given two points on a manifold with a given horizontal distribution, is there a smooth horizontal curve that joins them? Or more generally, there exists an absolutely continuous horizontal curve that joins them? To address this question, the present text will focus on **smooth distributions**, which are characterized by the property that for each point  $p \in M$ , there is an open neighborhood  $U$  of it on which there are smooth vector fields  $X_1, \dots, X_n : U \rightarrow TM$  that at each point of  $U$  form a base for the fiber of that point respect to the distribution (see definition 1).

With a smooth distribution  $\mathcal{H} \subset TM$ , it is said that a nonempty immersed submanifold  $N \subseteq M$  is a **integral manifold** of  $\mathcal{H}$  if  $T_p N = \mathcal{H}_p$  for all  $p \in N$ , *i.e.*, if the tangent space of all points of the submanifold is the fiber of the horizontal distribution. As an example, in the distribution given in example 3, the image of any integral curve of the vector field that determines the distribution over the manifold is an integral manifold for that distribution. A particular example of a distribution and its family of integral manifolds is given below.

*Example 4* (Orthogonal complement of radial vector field). Let  $\mathcal{G}$  be the distribution over  $\mathbb{R}^n$  determined by the radial vector field  $x^i \partial / \partial x^i$ , and let  $\mathcal{G}^\perp$  be its perpendicular bundle, *i.e.*, the distribution whose fibers are the orthogonal complement of the fibers of  $\mathcal{G}$ .  $\mathcal{G}^\perp$  is a distribution over  $\mathbb{R}^n$ , and the sphere centered on 0, of radius  $|x|$ , for all  $x \neq 0$  is an integral submanifold of  $\mathcal{G}^\perp$ .

There are cases of distributions over a manifold that do not have integral manifolds, as is shown in the following example, taken from [1], Ch. 19.

*Example 5* (Distribution without integral manifolds). Consider the distribution  $\mathcal{H}$  over  $\mathbb{R}^3$  spanned by the following vector fields:

$$X = \frac{\partial}{\partial x} + y \frac{\partial}{\partial z}, \quad Y = \frac{\partial}{\partial y}.$$

This distribution does not have integral manifolds. To see this, suppose that  $N$  is an integral manifold that contains an arbitrary point  $\mathbf{x} \in \mathbb{R}^3$ . Because  $X$  and  $Y$  are tangent to  $N$ , any integral curve of  $X$  or  $Y$  that starts in  $N$  stays in  $N$ , at least for a short time (*i.e.*, the integral curve  $\gamma$  must be defined over a sufficiently small interval such that its image is fully contained in  $N$ ).

Therefore, as the integral curve of  $X$  is a straight line contained in the plane that is parallel to the  $xz$ -plane, there is a segment of this line that is contained in  $N$ , and for every point in this segment, the integral curves of  $Y$  that passes through them are straight lines parallel to the  $y$ -axis, so there must be an open vicinity of  $\mathbf{x}$  that contains a plane generated by the segments of the integral curves of  $X$  and  $Y$  that passes through  $\mathbf{x}$  (see figure 1). However, the tangent plane at any point  $p$  of this plane off of the segment induced by the integral curve of  $X$  is not equal to  $\mathcal{H}_p$ , since  $X$  depends of  $y$ .

A concept that at first seems far away, but is useful for analyzing integrability of manifolds (defined below) is the idea of involutivity. A smooth distribution  $\mathcal{H}$  is said to be **involutive** if given any pair of smooth vector fields  $X, Y$  defined on a open subset of  $M$  that satisfy  $X_p, Y_p \in \mathcal{H}_p$ , their Lie bracket also satisfies the same condition, *i.e.*, it is tangent to the distribution in the given open subset.

FIGURE 1. Illustration of the planes generated at each point by the integral curves of the smooth vector fields that determine the distribution given in example 5.

The set of all smooth vector fields globally defined, tangent to the distribution  $\mathcal{H}$  is denoted as  $\Gamma(\mathcal{H})$ . It is clear from the definition of involutivity that if  $\mathcal{H}$  is involutive,  $\Gamma(\mathcal{H}) \subset \mathfrak{X}(M)$  is a Lie subalgebra. The converse is also true, and can be proven extending any pair of smooth vector fields locally defined, tangent to  $\mathcal{H}$ , to a pair of vector fields in  $\Gamma(\mathcal{H})$ , using an adequate bump function.

A smooth distribution  $\mathcal{H}$  over a manifold  $M$  is called **integrable** if each point of  $M$  is contained in an integral manifold of  $\mathcal{H}$ . It is clear then that *every integrable distribution is involutive*, because every pair of smooth vectors tangent to  $\mathcal{H}$ , defined over an open set  $U \subset M$ , satisfy that their Lie bracket is also tangent to  $\mathcal{H}$  in that open set, since there exists a integral manifold  $N$  of  $\mathcal{H}$  for every point of  $U$  such that the pair of smooth vectors are tangent to  $N$ , and in consequence, their Lie bracket is also tangent to  $N$ .

In fact, the involutivity condition does not need to be checked with all smooth vector fields on  $\Gamma(\mathcal{H})$ , but it suffices to check if the Lie brackets of pairs of smooth vector fields of the local frame that determines the distribution are tangent to it, since every smooth local frame tangent to  $\mathcal{H}$  is a linear combination of the smooth vector fields of the local frame.

Given a smooth distribution  $\mathcal{H} \subset TM$  of rank  $k$ , it is said that a smooth coordinate chart  $(U, \phi)$  of  $M$  is **flat for  $\mathcal{H}$**  if  $\phi(U)$  is a cube in  $\mathbb{R}^m$  (being  $m$  the dimension of  $M$ ), and at points of  $U$ ,  $\mathcal{H}$  is spanned by the first  $k$  coordinate vector fields  $\partial/\partial x^1, \dots, \partial/\partial x^k$  (see figure 2). The geometrical meaning of this property for a distribution is that, locally (in that chart), the manifold is homeomorphic to a cube in  $\mathbb{R}^m$ , and the vector subspaces induced by the distribution at each point fit together as affine spaces of dimension given by

FIGURE 2. Flat chart for a distribution.

the rank of the distribution in  $\mathbb{R}^m$ . Also, each slice of the form  $x^{k+1} = c^{k+1}, \dots, x^m = c^m$ , for constants  $c^{k+1}, \dots, c^m$  in the image of  $U$  of such a chart is an integral manifold of the distribution generated by  $\partial/\partial x^1, \dots, \partial/\partial x^k$ , and the preimage of this integral manifold is an integral manifold of  $\mathcal{H}$ , contained in  $U$ .

The case when every point in  $M$  has a coordinate chart centered in it, flat for  $\mathcal{H}$  is discussed in the following definition and geometrical interpretation.

**Definition 3** (Completely Integrable Distribution). A smooth distribution  $\mathcal{H} \subset TM$  is said to be **completely integrable** if there exists a flat chart for  $\mathcal{H}$  in a neighborhood of each point of  $M$ .

When a distribution is completely integrable, there is a coordinate chart centered at every point  $p \in M$ , such that the manifold locally looks like a cube in  $\mathbb{R}^m$ , and the distribution becomes the tangent subspace of dimension  $k$  generated by the first  $k$  vector fields that form the base of the tangent space at each point, as can be seen in figure 2.

Therefore, if a distribution is completely integrable, is then integrable, since there exists an integral manifold for each point (that in particular is a **maximal integral manifold**, as the dimension of this manifold coincides with the rank of the distribution), given by the integral manifold that contains this point in the image of the coordinate chart flat for  $\mathcal{H}$ . In this way, *if a distribution is completely integrable, it is integrable, and therefore involutive*. In fact, these implications are actually equivalences, thanks to Frobenius's theorem.

**Theorem 1** (Frobenius). *Every involutive distribution is completely integrable.*

*Proof.* ([1], Ch. 19) First, it will be shown that any involutive distribution is spanned by independent smooth commuting vector fields, and as a consequence of this fact, the distribution is completely integrable.

Let  $\mathcal{H}$  be an involutive distribution of rank  $k$  on an  $m$ -dimensional manifold  $M$ , and let  $p \in M$ . Let  $(U, \varphi)$  be a smooth coordinate chart centered in  $p$ . Then,  $\varphi(U) \subset \mathbb{R}^m$ , and let  $X_1, \dots, X_k$  be a smooth local frame for  $\mathcal{H}$  in  $U$ .

Now,  $\{d\varphi(X_i)\}_{i=1}^k$  is a set of linearly independent vector fields over  $\varphi(U)$ . One can reordinate the coordinates of  $\mathbb{R}^m$  to make  $\mathcal{H}'_{\varphi(p)}$  (understood as the fiber of the distribution whose local frame is given by  $\{d\varphi(X_i)\}_{i=1}^k$ ) complementary to the subspace generated by  $(\partial/\partial x^{k+1}|_{\varphi(p)}, \dots, \partial/\partial x^m|_{\varphi(p)})$ .

Let  $\pi : \mathbb{R}^m \rightarrow \mathbb{R}^k$  the projection onto the first  $k$  coordinates, that is,  $\pi(x^1, \dots, x^m) = (x^1, \dots, x^k)$ . This map induces a smooth (smooth because it is the composition  $\mathcal{H}' \hookrightarrow T\varphi(U) \xrightarrow{d\pi} T\pi(\varphi(U))$ ) bundle homomorphism  $d\pi : T\mathbb{R}^m \rightarrow \mathbb{R}^k$  that acts as follows:

$$d\pi \left( \sum_{i=1}^m v_i \frac{\partial}{\partial x^i} \Big|_{\varphi(q)} \right) = \sum_{i=1}^k v_i \frac{\partial}{\partial x^i} \Big|_{\pi(\varphi(q))}, \text{ for } q \in U.$$

By the choice of coordinates,  $\mathcal{H}'_{\varphi(p)} \subset T_{\varphi(p)}\mathbb{R}^m$  is complementary to the kernel of  $d\pi_{\varphi(p)}$ , so the restriction  $d\pi|_{\mathcal{H}'_{\varphi(p)}}$  is bijective. By continuity, the same is true for  $d\pi|_{\mathcal{H}'_{\varphi(q)}}$ , with  $q \in U$ , and therefore, the matrix entries of  $\left(d\pi|_{\mathcal{H}'_{\varphi(q)}}\right)^{-1} : T_{\pi(\varphi(q))}\mathbb{R}^k \rightarrow \mathcal{H}'_{\varphi(q)}$  are smooth, which makes the map smooth. With this in mind, the set of vector fields  $V_1, \dots, V_k$ , defined by

$$V_i|_{\varphi(q)} = \left(d\pi|_{\mathcal{H}'_{\varphi(q)}}\right)^{-1} \frac{\partial}{\partial x^i} \Big|_{\pi(\varphi(q))}$$

are a local frame of  $\mathcal{H}'$ . It is in fact a smooth commuting local frame, as will be seen below.

First, notice that  $V_i$  and  $\partial/\partial x^i$  are  $\pi$ -related, for  $i = 1, \dots, k$ , because

$$\frac{\partial}{\partial x^i} \Big|_{\pi(\varphi(q))} = d\pi|_{\mathcal{H}'_{\varphi(q)}}(V_i|_{\varphi(q)}) = d\pi_{\varphi(q)}(V_i|_{\varphi(q)}),$$

so by the naturality of Lie brackets,

$$d\pi_{\varphi(q)}([V_i, V_j]_{\varphi(q)}) = \left[ \frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j} \right]_{\pi(\varphi(q))} = 0,$$

but as  $d\pi|_{\mathcal{H}'_{\varphi(q)}}$  is injective and  $[V_i, V_j]_{\varphi(q)} \in \mathcal{H}'_{\varphi(q)}$ , since  $\mathcal{H}$  is involutive,  $[V_i, V_j]_{\varphi(q)} = 0$  for all  $q \in U$ , so  $\{V_i\}_{i=1}^k$  form a smooth commuting frame for  $\mathcal{H}'$ , and  $\{d\varphi^{-1}(V_i)\}_{i=1}^k$  are a smooth commuting local frame for  $\mathcal{H}$ .

Finally, to show that the existence of the commuting frame  $\{V_i\}_{i=1}^k$  for  $\mathcal{H}'$  is a sufficient condition for  $\mathcal{H}$  to be completely integrable, let  $\theta_i$  be the flow of  $V_i$ ,  $i = 1, \dots, k$ . There is a neighborhood  $W$  of  $\varphi(p)$ , contained in  $\varphi(U)$  such that the composition  $(\theta_1)_{t_1} \circ (\theta_2)_{t_2} \circ \dots \circ (\theta_k)_{t_k}$  is well defined, for sufficiently small  $t_1, \dots, t_k$  ( $|t_i| < \epsilon$ , for an adequate  $\epsilon > 0$ ). Define  $\Omega \subset \mathbb{R}^{m-k}$  as

$$\Omega = \{(s^{k+1}, \dots, s^m) \in \mathbb{R}^{m-k} : (0, \dots, 0, s^{k+1}, \dots, s^m) \in W\},$$

and  $\Phi : (-\epsilon, \epsilon) \times \Omega \rightarrow \varphi(U)$  as

$$\Phi(s^1, \dots, s^k, s^{k+1}, \dots, s^m) = (\theta_1)_{s^1} \circ \dots \circ (\theta_k)_{s^k}(0, \dots, 0, s^{k+1}, \dots, s^m).$$

Notice that, by construction,  $\Phi(\{0\}^k \times \Omega) = (0^k \times \mathbb{R}^{m-k}) \cap W$ . Moreover,  $\partial/\partial s^i$  and  $V_i$  are  $\Phi$ -related for  $i = 1, \dots, k$ , because, as the flows commute, for a given  $s^0 = (s^1, \dots, s^m) \in (-\epsilon, \epsilon)^k \times \Omega$ ,

$$\begin{aligned} d\Phi_{s^0} \left( \frac{\partial}{\partial s^i} \Big|_{s^0} \right) f &= \frac{\partial}{\partial s^i} \Big|_{s^0} f \left( \Phi(s^1, \dots, s^m) \right) \\ &= \frac{\partial}{\partial s^i} \Big|_{s^0} f \left( (\theta_1)_{s^1} \circ \dots \circ (\theta_k)_{s^k}(0, \dots, 0, s^{k+1}, \dots, s^m) \right) \\ &= \frac{\partial}{\partial s^i} \Big|_{s^0} f \left( (\theta_i)_{s^i} \circ \dots \circ (\theta_{i-1})_{s^{i-1}} \circ (\theta_{i+1})_{s^{i+1}} \circ \dots \right. \\ &\quad \left. \circ (\theta_k)_{s^k}(0, \dots, 0, s^{k+1}, \dots, s^m) \right), \end{aligned}$$

and for any  $q \in \varphi(U)$ ,  $t \mapsto (\theta_i)_t(q)$  is an integral curve of  $V_i$ , so the above expression is equal to  $V_i|_{\Phi(s^0)}f$ , which shows that  $\partial/\partial s^i|_{s^0}$  and  $V_i$  are  $\Phi$ -related.

By the previous computations,

$$d\Phi_0 \left( \frac{\partial}{\partial s^i} \Big|_0 \right) = V_i|_{\varphi(p)}, \quad i = 1, \dots, k,$$

and on the other hand, since  $\Phi(0, \dots, 0, s^{k+1}, \dots, s^m) = (0, \dots, 0, s^{k+1}, \dots, s^m)$ , it follows that

$$d\Phi_0 \left( \frac{\partial}{\partial s^i} \Big|_0 \right) = \frac{\partial}{\partial x^i} \Big|_{\varphi(p)}, \quad i = k+1, \dots, m.$$

Therefore,  $d\Phi_0$  takes the basis  $(\partial/\partial s^1|_0, \dots, \partial/\partial s^m|_0)$  of  $T_0\mathbb{R}^m$  to the basis  $(V_1|_{\varphi(p)}, \dots, V_k|_{\varphi(p)}, \partial/\partial x^{k+1}|_{\varphi(p)}, \dots, \partial/\partial x^m|_{\varphi(p)})$  of  $T_{\varphi(p)}\varphi(U)$ . By the inverse function theorem,  $\Phi$  is a local diffeomorphism (in a neighborhood of 0), and  $\phi = \Phi^{-1}$  is a smooth coordinate chart that takes  $V_i$  to  $\partial/\partial s^i$ , for  $i = 1, \dots, k$ , and takes  $\partial/\partial x^i$  to  $\partial/\partial s^i$ , for  $i = k+1, \dots, m$ . Thus, the smooth coordinate chart flat for  $\mathcal{H}$  in a vicinity of  $p \in M$  is  $\phi \circ \varphi$ , and since this is independent of  $p$ , for every point there is a smooth coordinate chart flat for  $\mathcal{H}$ , what makes  $\mathcal{H}$  a completely integrable distribution.  $\square$

The next proposition is one of the main consequences of Frobenius theorem, and it is fundamental to study foliations, topic that is going to be discussed below.

**Proposition 2** (Local structure of integral manifolds). *Let  $\mathcal{H}$  be an involutive distribution of rank  $k$  on a smooth manifold  $M$ , and let  $(U, \varphi)$  be a flat chart for  $\mathcal{H}$ . If  $N$  is any connected integral manifold of  $\mathcal{H}$ , then  $\varphi(U \cap N)$  is the union of countably many disjoint open subsets of parallel  $k$ -dimensional slices of  $\varphi(U)$ , whose preimages are open in  $N$  and embedded in  $M$ .*

*Proof.* ([1], Ch. 19) Let  $N$  be an integral manifold of  $\mathcal{H}$ . Since the inclusion map  $\iota : N \hookrightarrow M$  is continuous,  $\varphi(\iota^{-1}(U)) = \varphi(N \cap U)$  is open in  $\varphi(N)$ . Then,  $\varphi(U \cap N)$  is the union of open slices (*i.e.*, open subsets of a slice of  $\varphi(U)$ ) with  $x_i = \text{constant}$ , for  $i = k+1, \dots, m$ . Moreover, this union is at most countable, because  $N$  is second countable, and since

FIGURE 3. Local structure of an integral manifold.

$\varphi(N \cap U)$  is a union of open slices,  $\pi(\varphi(U \cap N))$  consists of a countable number of points (recall that  $\pi : \varphi(U) \rightarrow \mathbb{R}^{m-k}$  is the projection onto the last  $m - k$  coordinates) in  $\mathbb{R}^{m-k}$ , which implies that the union of open slices is at most countable.

Finally, if  $V$  is an open slice in the slice  $S$ , the inclusion map  $\varphi^{-1}(V) \hookrightarrow M$  is a smooth embedding, because it is the composition of smooth embeddings  $\varphi^{-1}(V) \hookrightarrow \varphi^{-1}(S) \hookrightarrow M$ .  $\square$

The last proposition implies that one can put all the maximal integral manifolds of an involutive distribution of rank  $k$  together, to obtain a partition on  $M$  into  $k$ -dimensional submanifolds, that satisfy the following definition.

**Definition 4** (Flat chart for a collection of submanifolds). A smooth chart  $(U, \varphi)$  for  $M$  is called **flat for a collection  $\mathcal{F}$  of  $k$ -dimensional submanifolds of  $M$**  if  $\varphi(U)$  is a cube in  $\mathbb{R}^m$ , and the image of each submanifold via  $\varphi$  intersects  $\varphi(U)$  in either the empty set or in a countable union of  $k$ -dimensional slices of the form  $x^{k+1} = c^{k+1}, \dots, x^m = c^m$ .

**Definition 5** (Foliation over a manifold). A foliation of dimension  $k$  on a smooth manifold  $M$  is a collection  $\mathcal{F}$  of disjoint, connected, nonempty, immersed  $k$ -dimensional submanifolds of  $M$  (called the **leaves** of the foliation), whose union is  $M$ , and such that in a neighborhood of each point  $p \in M$  there is a flat chart for  $\mathcal{F}$ .

The following are examples of foliations over a manifold, mainly taken from [1], Ch. 19.

*Example 6* (Collection of affine subspaces). The collection of all  $k$ -dimensional affine subspaces of  $\mathbb{R}^m$  parallel to  $\mathbb{R}^k \times \{0\}$  is a  $k$ -dimensional foliation for  $\mathbb{R}^m$ .

*Example 7* (Spheres centered at the origin). The collection of all spheres centered at 0 is an  $(m - 1)$ -dimensional foliation of  $\mathbb{R}^m \setminus \{0\}$ .

*Example 8* (Cartesian product of manifolds). If  $M$  and  $N$  are connected smooth manifolds, the collection of subsets of the form  $M \times \{q\}$ , with  $q \in N$ , is a foliation of  $M \times N$ , each of whose leaves is diffeomorphic to  $M$ .

From the definition of foliations, it is clear that if  $\mathcal{F}$  is a foliation on a smooth manifold  $M$ , the collection of tangent spaces to the leaves of  $\mathcal{F}$  forms an involutive distribution on  $M$ . In a reciprocal way, the collection of maximal integral manifolds of an involutive distribution forms a foliation over the manifold, as it is stated in the global Frobenius theorem.

**Theorem 2** (Global Frobenius theorem). *Let  $\mathcal{H}$  be an involutive distribution on a smooth manifold  $M$ . The collection of all maximal connected integral manifolds of  $\mathcal{H}$  forms a foliation of  $M$ .*

Following the procedure of [1], Ch.19, the next lemma is going to be used in the proof of this theorem.

**Lemma 1.** *Suppose  $\mathcal{H} \subset TM$  is an involutive distribution, and let  $\{N_\alpha\}_{\alpha \in A}$  be any collection of connected integral manifolds of  $\mathcal{H}$  with a point in common. Then,  $N = \bigcup_\alpha N_\alpha$  has a unique smooth manifold structure making it into a connected integral manifold of  $\mathcal{H}$ .*

*Proof of the global Frobenius theorem.* ([1], Ch. 19) For each  $p \in M$ , let  $L_p$  be the union of all connected integral manifolds of  $\mathcal{H}$  containing  $p$ . By the preceding lemma,  $L_p$  is a connected integral manifold of  $\mathcal{H}$  containing  $p$ , and it is clearly maximal. By maximality, if  $L_p$  and  $L_{p'}$  intersect,  $L_p = L_{p'}$ , because  $L_p \cup L_{p'}$  is an integral manifold containing both  $p$  and  $p'$ . Thus, the maximal connected integral manifolds are either disjoint or identical.

If  $(U, \varphi)$  is any flat chart for  $\mathcal{H}$ , then  $\varphi(L_p \cap U)$  is a countable union of open subsets of slices (by proposition 2). For any such slice  $S$ , if  $\varphi(U \cap L_p) \cap S$  is neither empty nor all of  $S$ , then  $L_p \cup \varphi^{-1}(S)$  is a connected integral manifold properly containing  $L_p$ , which contradicts the maximality of  $L_p$ . Therefore,  $\varphi(L_p \cap U)$  is precisely a countable union of slices, so the collection  $\{L_p : p \in M\}$  is the desired foliation.  $\square$

With the global Frobenius theorem, one can address the question at the start of this subsection: in general, for an given distribution there is not a smooth horizontal curve that connects an arbitrary pair of points, because the points can be in different leaves of the foliation given by the distribution.

*Example 9* (Foliations on a torus). The torus  $T = \mathbb{S}^1 \times \mathbb{S}^1$  can be endowed with the distribution induced by the cartesian product of manifolds (see example 8). In this case, the foliation is conformed by copies of  $\mathbb{S}^1$ . The horizontal curves are segments of this copies, and if two points lay in different copies, there is not a horizontal curve that connects them.

## 2. SUBRIEMANNIAN GEOMETRY

**2.1. Subriemannian Structure and Geodesics.** If a distribution is doted with a fiber inner-product, the pair of a manifold and a distribution over it defines a subriemannian structure, as is stated in the following definition.

**Definition 6** (Subriemannian Structure). A subriemannian structure over a manifold  $M$  is a distribution  $\mathcal{H} \subset TM$ , called horizontal distribution, endowed with a fiber inner-product  $\langle \cdot, \cdot \rangle$  on this subbundle, which is a positive definite smooth quadratic form, belonging to the smooth sections of the smooth bundle  $T_0^2 M \xrightarrow{\pi} M$ . ((2,0) tensor fields over a manifold).

Some examples of subriemannian structures are given below.

*Example 10* (Riemannian Structure). Every riemannian structure is in particular a subriemannian structure, where the distribution is all the tangent bundle.

*Example 11* (Heisenberg Group). The distribution of the Heisenberg group is commented in example 2. The inner product over a fiber  $\mathcal{H}_{(x,y,z)}$ , with  $(x,y,z) \in \mathbb{R}^3$  is given by  $\langle \cdot, \cdot \rangle: \mathcal{H}_{(x,y,z)} \times \mathcal{H}_{(x,y,z)} \rightarrow \mathbb{R} : (v,w) \mapsto v_1 w_1 + v_2 w_2$ , where  $v = (v_1, v_2, v_3)$  and  $w = (w_1, w_2, w_3)$ .

*Example 12* (Vector Field over a Manifold). As seen in example 3, any smooth vector field  $X: M \rightarrow TM$  that does not cancel out in any point determines a distribution. The fiber inner-product  $\langle \cdot, \cdot \rangle: \mathcal{H}_p \times \mathcal{H}_p \rightarrow \mathbb{R}$  for  $p \in M$  is given by  $\langle \lambda_1 X_p, \lambda_2 X_p \rangle = \lambda_1 \lambda_2$ .

In the particular case of the horizontal curves, one can define the **length of a horizontal smooth curve**  $\gamma$  (denoted by  $\ell(\gamma)$ ) as in the case of riemannian geometry:

$$\ell(\gamma) = \int \|\dot{\gamma}\| dt,$$

since the tangent vectors of the curve at all points are in the fibers of the horizontal distribution, where there is a inner product defined, and  $\|\dot{\gamma}\| = \sqrt{\langle \dot{\gamma}, \dot{\gamma} \rangle}$ .

With the idea of length of horizontal curves, the **distance between two points**  $p, q \in M$ , denoted by  $d(p, q)$ , is defined as the infimum of the lengths of all absolutely continuous horizontal curves that begin in  $p$  and end in  $q$ , that is,

$$d(p, q) = \inf \{ \ell(\gamma) \mid \gamma: [0, 1] \rightarrow M \text{ is absolutely continuous and } \gamma(0) = p, \gamma(1) = q \}.$$

The distance between two points is said to be infinite if there is no curve joining them. Also, in analogy with riemannian geometry, an absolutely continuous horizontal curve that realizes the distance between two points is called a **geodesic**.
